Test Case Generation from a Z Specification of the Landing Gear System

Maximiliano Cristiá
CIFASIS and UNR, Rosario, Argentina
cristia@cifasis-conicet.gov.ar

In this technical report we present the results of a case study on the application of a model-based testing method (MBT) to a real-world problem from the aviation industry. The requirements were proposed by engineers working for the European aviation industry and comprise the landing gear system (LGS) of an aircraft. We developed a complete Z specification of the control software of the LGS. Then, we automatically generated abstract test cases by applying FASTEST (a tool implementing the Test Template Framework, which is a MBT method). These test cases cover all the functional and real-time scenarios described in the requirements. The manual work required to generate them is minimum.

1 Introduction

This answer to the case study shows how (abstract) test cases can be (almost) automatically generated from a Z specification of the landing gear system (LGS). In this way, the cost of writing the specification is paid-off by using the specification not only to produce the implementation but also to test it. Test case generation from a formal specification is within the scope of model-based testing (MBT). There are many different MBT methods to generate test cases [20, 26, 5]. Some of them use Z as the modeling language but there are methods for other formal (and semi-formal) notations, including some within the scope of ABZ 2014.

In this technical report a particular MBT method known as the Test Template Framework is used. The TTF uses Z as the modeling language and is particularly oriented towards functional unit testing [37]. Recently tool support for the TTF was provided by Fastest [11]. Even more recently Fastest started to use \{log\} (pronounced ‘setlog’) as a test case generator [13]. \{log\} is a Constraint Logic Programming (CLP) language that embodies the fundamental forms of set designation and a number of
primitive operations for set management. Fastest automates most of the steps of a TTF testing campaign up to the production of abstract test cases. Hence, the Z specification of the LGS was loaded in Fastest to automatically generate test cases.

Test cases produced by Fastest are abstract test cases in the sense that they are pieces of Z text. In other words, the variables and constants participating in one of these test cases are defined at the Z level. Hence, these test cases cannot be provided to the implementation of the LGS. However, they can be semi-automatically refined to the implementation by writing so-called refinement rules in a simple language that allows engineers to connect abstract test cases with the implementation technology [12]. Test case refinement is out of the scope of this document and currently is not fully implemented in Fastest.

The Z specification presented here specifies only the controlling software [6, Sect. 4]. It was not formally verified basically due to resource availability. However, it would be desirable to prove that it verifies some state invariants and, more importantly, that it verifies the expected properties proposed by the designers of the LGS [6, Sect. 5]. Had the authors have the time for such verification they would have used the Z/EVES theorem prover [33]. However, to be able to prove some of these properties it would be necessary to specify some domain properties described in the requirements document [6, Sect. 3] and perhaps the extensions to the Z notation proposed by Evans [16] would also be necessary.

This technical report introduces many concepts (such as MBT, the Z notation, the TTF, etc.) to make it self-contained. It also includes the complete list of the satisfiable test conditions (Appendix A) and abstract test cases (Appendix B) automatically generated by Fastest.

1.1 Introduction to Model-Based Testing

Software construction has proved to be more complex than expected. Most often software projects run beyond budget, are delivered late and having many errors. Only an insignificant portion of the products of the software industry are sold with warranty. There is a number of reasons for this state of the practice, but companies usually complain about the costs of software verification as the cause of not doing it thoroughly [8, page 20] [3, page 88] [30, page 157] [27] [32, table ES-1 at page ES-5]. Reducing the costs of verification would imply more projects within budget and less errors. One of the most promising strategies for reducing the costs of verification is making it as automatic as possible. On the other hand, the software industry relies almost exclusively on testing to perform the functional verification of its products. Currently, testing is essentially a manual activity that automates only the most trivial tasks [28] [32].

1.1.1 Software Testing

Software testing can be defined as the dynamic verification of a program by running it on a finite set of carefully chosen test cases, from the usually infinite input domain, and comparing the actual behavior with respect to the expected one [15] [38]. We want to remark the following:

- Testing implies running the program as opposed to, say, static analysis performed on the source code.
- The set of test cases on which the program will be executed is finite and usually very small, compared with the size of the input domain.
- These test cases must be selected, i.e. there are some criteria or rules that must be followed in order to chose test cases. It would be wrong a selection process guided by the mood of the engineer.
The output produced by the program for each test case must be compared with the expected output. If both agree then the program is correct on that test case; otherwise some error has been found. The artefact that helps to decide the presence of an error is called oracle.

Many qualities of a program can be tested. For example, performance, portability, usability, security and so on. Although they are all important, functional correctness is perhaps the one on which industry pays more attention. In many contexts, for instance, performing poorly is bad but performing wrongly is worse.

Traditionally, the testing process has been divided into five steps as shown in Figure 1. The idea is to start testing small portions of the system under test (SUT) called units—usually they are subroutines, procedures or functions—in such a way that once they have passed all the tests, they are progressively assembled together. As new units are integrated, the resulting modules are tested. Sometimes it is possible to independently test subsystems of the SUT. Finally, the full system is tested by users. In this way, errors are discovered as earlier as possible.

Fastest focuses on improving a particular unit testing method and providing tool support for the selection of functional test cases for it, as we will shortly see.

### 1.1.2 Functional Correctness and Formal Specifications

The last item above suggests that there must be some way of determining what the expected output of a program is. In other words, there should be a way of determining whether the program is functionally correct or not. The classical definition of functional correctness is: a program is functionally correct if it behaves according to its functional specification [19, page 17]. This means that two documents or descriptions are needed to perform functional verification: the program itself and its functional specification. In turn, this implies that functional testing is possible only if a specification of the program or SUT is present. The functional specification is sometimes used as the oracle because it is, in fact, the definition of correctness for its implementation.

Furthermore, if automation of the testing process is the goal, then some kind of formal specification is mandatory because otherwise mechanical analysis of the specification becomes unfeasible, turning testing automation unrealistic. A specification is formal if it is written in a formal notation or language.
Formal notations or formalisms for specifying software systems are known as formal methods and have a long and well-established tradition within the Software Engineering community \[7, 22\].

Fastest focuses on functional testing based on a formal functional specification of the SUT.

### 1.1.3 Model-Based Testing

When testing and formal specifications are combined we enter into the scope of Model-Based Testing (MBT). MBT is a well-known technique aimed at testing software systems analyzing a formal model or specification of the SUT \[38, 21\]. That is, MBT approaches generate test cases from the formal specification of the SUT. The fundamental hypothesis behind MBT is that, as a program is correct if it satisfies its specification, then the specification is an excellent source of test cases.

One of the possible processes of testing a system through a MBT method is depicted in Figure 2. The first step is to analyze the model of the SUT looking for abstract test cases. Usually, MBT methods divide this step into two activities: firstly, test specifications are generated, and, secondly, abstract test cases are derived from them. Although the form of test specifications depends on the particular MBT method, they can be thought as sets of abstract test cases. Test cases produced during the “Generation” step are abstract in the sense that they are written in the same language of the model, making them, in most of the MBT methods, not executable. In effect, during the “Refinement” step these abstract test cases are made executable by a process that can be called refinement, concretization or reification. Note that this not necessarily means that the SUT has been refined from the model; it only says that abstract test cases must be refined. Once test cases have been refined they have to be executed by running the program on each of them. In doing so, the program produces some output for each test case. At this point, some way of using the model as an oracle, to decide whether a given test case has found an error or not, is needed. There are two possibilities depending on the MBT method and the formal notation being used:

1. When the model is analyzed during the “Generation” step, each abstract test case is bound to its corresponding expected result. Later, these expected results are refined along the same lines of test cases. Finally, the actual output of the program is compared with the result of refining the expected results.

2. The output produced by the SUT for each test case is abstracted at the level of the specification. Then, each abstract test case and its corresponding abstract(ed) output are replaced in the specification. If the specification reduces to true then no error was found; if it reduces to false then an error was found.

MBT has been applied to models written in different formal notations such as Z \[37\], Finite State Machines (FSM) and their extensions \[20\], B \[26\], algebraic specifications \[5\], and so on. However, most of the work has focused on the “Generation” step from some variant of FSM for system testing \[21, 29\]. One of the greatest advantages of working with FSM lays in the degree of automation that can be achieved by many MBT methods. On the other hand, FSM pose a strong limit on the kind of systems that can be specified.

Fastest provides support for the “Generation” step from Z specifications as a way to widen the class of systems that can be specified.
2 Introduction to the Z Notation

Here we introduce the Z notation by means of an example. It is assumed that the reader is fluent in predicate logic and discrete mathematics. Z is introduced just to the point needed to read the rest of this document; for deeper presentations consult any textbook on Z. The Z notation is a formal method based on first-order logic and Zermelo-Fraenkel set theory that has been extensively studied and applied to a range of software systems [22, 2]. There are two slightly different versions of the language. The first to appear is known as the Spivey version [35], and the second one is referred as Standard Z because it is the result of a standardization process carried out by ISO [23]. We will use the second one.

2.1 The Requirements

Think in the savings accounts of a bank. Each account is identified by a so-called account number. Clients can share an account and each client can own many accounts—some of which might be shared with other clients, and some not. The bank requires to keep record of just the balance of each account, and the ID and name of each client. Any person can open an account in the bank becoming its first owner. Owners can add and remove other owners and can withdraw money from their accounts and check the balance of their accounts. Any person can deposit money in any account.

2.2 The Form of a Z Specification

The Z language can be used in different ways but there is a de-facto usage style. Any Z specification takes the form of a state machine—not necessarily a finite one. This machine is defined by giving its state space and the transitions between those states. The state space is given by declaring a tuple of typed state variables. A transition, called operation in Z, is defined by specifying its signature, its preconditions and its postconditions. The signature of an operation includes input, state and output variables. Each
operation can change the state of the machine. State change is described by giving the relation between before-state and after-state variables.

### 2.3 Basic Types

As we have said, each savings account is identified by an account number. We need a way to name these account numbers. Since account numbers are used just as identifiers we can abstract them away, not caring about their internal structure. Z provides so-called basic or given types for these cases. The Z syntax for introducing a basic type is:

\[ \text{ACCNUM} \]

In this way, it is possible to declare variables of type \text{ACCNUM} and it is possible to build more complex types involving it—for instance the type of all sets of account numbers is \( \mathbb{P} \text{ACCNUM} \). Along the same lines, we introduce basic types for the ID’s of clients and their names:

\[ \text{UID}, \text{NAME} \]

We represent the money that clients can deposit and withdraw and the balance of savings accounts as natural numbers. We think that specifying them as real numbers does not add any significant detail to the model, but makes it truly complicated since Z does not provides a native type for real numbers. If the decimal positions are really needed, then we can think that each natural number used in the specification is the result of multiplying the corresponding real number by a convenient power of 10—for instance, all amounts of money are multiplied by 100. The type for the integer numbers, \( \mathbb{Z} \), is built-in in Z. The notation also includes the set of natural numbers, \( \mathbb{N} \). Then, we define:

\[
\text{MONEY} == \mathbb{N} \\
\text{BALANCE} == \mathbb{N}
\]

In other words, we introduce two synonymous for the set of natural numbers so the specification is more readable.

### 2.4 The State Space

The state space is defined as follows:

\[
\begin{align*}
\text{Bank} & \\
\text{clients} : \text{UID} & \leftrightarrow \text{NAME} \\
\text{balances} : \text{ACCNUM} & \leftrightarrow \text{BALANCE} \\
\text{owners} : \text{UID} & \leftrightarrow \text{ACCNUM}
\end{align*}
\]

This construction is called schema; each schema has a name that can be used in other schemas. In particular this is a state schema because it only declares state variables. In effect, it declares three state variables by giving their names and types. Each state of the system corresponds to a particular valuation of these three variables. The type constructor \( \leftrightarrow \) defines partial function.\(^1\) Then, \text{clients} is a partial

---

\(^1\)It must be noted that the Z type system is not as strong as the type systems of other formalisms, such as Coq.\(^2\) So we will be as formal as is usual in the Z community regarding its type system.
function from $UID$ onto $NAME$. It makes sense to define such a function because each person has a unique $UID$ but not a unique name; and it makes sense to make $clients$ partial because not every person is a client of the bank all the time. The same is valid for $balances$: there is a functional relationship between account numbers and balances, and not all the account numbers are used all the time in the bank. The symbol $\leftrightarrow$ defines binary relations. It is correct to define $owners$ as a relation, and not as a function, because a given client may own more than one account and each savings account may be owned by many clients.

Now, we can define the initial state of the system as follows:

\[
\text{InitBank}
\]
\[
\text{Bank}
\]
\[
\begin{align*}
\text{clients} & = \emptyset \\
\text{balances} & = \emptyset \\
\text{owners} & = \emptyset
\end{align*}
\]

$InitBank$ is another schema. The upper part is the declaration part and the lower part is the predicate part—this one is optional and is absent from $Bank$. In the declaration part we can declare variables or use schema inclusion. The latter means that we can write the name of another schema instead of declaring their variables. This allows us to reuse schemas. In this case the predicate part says that each variable is equal to the empty set. It is important to remark that the $=$ symbol is logical equality and not an imperative assignment—Z has no notion of control flow. In Z, relations and functions are sets of ordered pairs. Being sets they can be compared with the empty set. The symbol $\emptyset$ is polymorphic in Z: it is the same for all types.

Since in Z each variable has a type, all the expressions are typed and then it is possible to implement a type-checker for the language [33, 17].

2.5 Opening the First Savings Account

Now we can start defining each operation of the system. In order to keep this introduction short we specify just one operation and in doing so we introduce some more Z concepts. The operation describes how the first savings account is opened for a given person requesting it.

\[
\text{NewClientOk}
\]
\[
\Delta Bank
\]
\[
\begin{align*}
\text{u?} & : \text{UID} \\
\text{name?} & : \text{NAME} \\
\text{n?} & : \text{ACCNUM}
\end{align*}
\]
\[
\begin{align*}
\text{u?} & \notin \text{dom clients} \\
\text{n?} & \notin \text{dom balances} \\
\text{clients}' & = \text{clients} \cup \{\text{u?} \mapsto \text{name?}\} \\
\text{balances}' & = \text{balances} \cup \{\text{n?} \mapsto 0\} \\
\text{owners}' & = \text{owners} \cup \{\text{u?} \mapsto \text{n?}\}
\end{align*}
\]

The expression $\Delta Bank$ in the declaration part is a shorthand for including the schemas $Bank$ and $Bank'$. We already know what it means including $Bank$. $Bank'$ is equal to $Bank$ but all of its variables
are decorated with a prime. Therefore, \( \text{Bank} \) declares \( \text{clients}', \text{balances}' \) and \( \text{owners}' \) of the same types than those in \( \text{Bank} \). When a state variable is decorated with the prime it is assumed to be an after-state variable. The net effect of including \( \Delta \text{Bank} \) is, then, the declaration of three before-state variables and three after-state variables. A \( \Delta \) expression is included in every operation schema that produces a state change.

Variables decorated with a question mark, like \( u? \), are assumed to be input variables. Then, \( u? \) represents the ID of the person willing to open a savings account in the bank, and \( \text{name}? \) is his/her name. To simplify the specification a little bit we assume that a bank’s clerk provides the account number, \( n? \), when the operation is called—instead of the system generating it.

Note that the predicate part consists of five atomic predicates. When two or more predicates are in different rows they are assumed to be a conjunction. In other words, for instance:

\[
\begin{align*}
u? &\notin \text{dom clients} \\
n? &\notin \text{dom balances}
\end{align*}
\]

is equivalent to:

\[
u? \notin \text{dom clients} \land n? \notin \text{dom balances}
\]

\( Z \) uses the standard symbols of discrete mathematics and set theory so we think it will not be difficult for the reader to understand each predicate. Remember that functions and relations are sets of ordered pairs so they can participate in set expressions. For instance, \( \text{balances} \cup \{n? \mapsto 0\} \) adds an ordered pair to \( \text{clients} \). Again, the expression \( \text{balances}' = \text{balances} \cup \{n? \mapsto 0\} \) is actually a predicate saying that \( \text{balances}' \) is equal to \( \text{balances} \cup \{n? \mapsto 0\} \), and not that the latter is assigned to \( \text{balances}' \). In other words, this predicate says that the value of \( \text{balances} \) in the after-state is equal to the value of \( \text{balances} \) in the before-state plus the ordered pair \( n? \mapsto 0 \).

Note that operations are defined by giving their preconditions and postconditions. In \( \text{NewClientOk} \) the preconditions are:

\[
\begin{align*}
u? &\notin \text{dom clients} \\
n? &\notin \text{dom balances}
\end{align*}
\]

while its postconditions are:

\[
\begin{align*}
\text{clients}' &= \text{clients} \cup \{u? \mapsto \text{name}?\} \\
\text{balances}' &= \text{balances} \cup \{n? \mapsto 0\} \\
\text{owners}' &= \text{owners} \cup \{u? \mapsto n?\}
\end{align*}
\]

Therefore, \( \text{NewClientOK} \) does not say what the system shall do when \( u? \notin \text{dom clients} \land n? \notin \text{dom balances} \) does not hold. The bank says that nothing has to be done when either the person requesting the account is already a client or when the account number chosen by the clerk is already in use. Then, we define a new schema for the first case:

\[
\text{ClientAlreadyExists} \equiv [\exists \text{Bank}; u? : \text{UID} | u? \in \text{dom clients}]
\]

This is another way of writing schemas, called horizontal form. It has the same meaning than:
The expression $\Xi Bank$ is a shorthand for:

$$
\Xi Bank
$$

$$
\Delta Bank
$$

$$
\begin{align*}
\text{clients}' &= \text{clients} \\
\text{balances}' &= \text{balances} \\
\text{owners}' &= \text{owners}
\end{align*}
$$

If a $\Xi$ expression is included in an operation schema, it means that the operation will not produce a state change because all the primed state variables are equal to their unprimed counterparts. When a schema whose predicate part is not empty is included in another schema, the net effect is twofold: (a) the declaration part of the former is included in the declaration part of the latter; and (b) the predicate of the former is conjoined to the predicate of the latter. Hence, $\text{ClientAlreadyExists}$ could have been written as follows:

$$
\begin{align*}
\text{clients}, \text{clients}' : \text{uid} &\rightarrow \text{name} \\
\text{balances}, \text{balances}' : \text{accnum} &\rightarrow \text{balance} \\
\text{owners}, \text{owners}' : \text{uid} &\leftrightarrow \text{accnum} \\
\text{u?} : \text{uid}
\end{align*}
$$

$$
\begin{align*}
\text{u?} \in \text{dom clients} \\
\text{clients}' &= \text{clients} \\
\text{balances}' &= \text{balances} \\
\text{owners}' &= \text{owners}
\end{align*}
$$

We define the following schema for the negation of the remaining precondition:

$$
\text{AccountAlreadyExists} == [\Xi Bank; \text{n?} : \text{accnum} | \text{n?} \in \text{dom balances}]
$$

Usually, schemas like $\text{NewClientOk}$ are said to specify the successful cases or situations, while schemas like $\text{ClientAlreadyExists}$ and $\text{AccountAlreadyExists}$ specify the erroneous cases. Finally, we assemble the three schemas to define the total operation—i.e. an operation whose precondition is equivalent to $true$—for a person opening his/her first savings account in the bank:

$$
\text{NewClient} == \\
\text{NewClientOk} \\
\lor \text{ClientAlreadyExists} \\
\lor \text{AccountAlreadyExists}
$$
NewClient is defined by a so-called schema expression. Schema expressions are expressions involving schema names and logical connectives. They can be very complex but we will not need all this complexity in this thesis. Let \( A \) be the schema defined as \([D_A | P_A]\) where \( D_A \) is the declaration part and \( P_A \) is its predicate. Similarly, let \( B \) the schema defined by \([D_B | P_B]\). Then, the schema \( C \) defined by \( A \oplus B \), where \( \oplus \) is any of \( \land, \lor \) and \( \Rightarrow \), is the schema \([D_A; D_B | P_A \oplus P_B]\). In other words, the declaration parts of the schemas involved in a schema expression are joined together and the predicates are connected with the same connectors used in the expression—if there is some clash in the declaration parts it must be resolved by the user. In symbols:

\[
A == [D_A | P_A] \\
B == [D_B | P_B] \\
C == A \oplus B, \text{ where } \oplus \text{ is any of } \land, \lor, \Rightarrow \text{ then} \\
C == [D_A; D_B | P_A \oplus P_B]
\]

Essentially, this is all the reader needs to know about Z to understand the rest of this thesis. Actually, Fastest, the tool we have developed, does not support the whole language, but it does support a fully expressive subset, as we discuss in Chapter ???. Therefore, we now introduce the rest of the savings account specification but including informal comments only when some new Z feature is introduced.

### 2.6 State Invariants

A predicate is said to be a state invariant if it holds in every state of the system. The usual Z style includes state invariants in the state schema. For example, the state schema for the savings account system would have been:

\[
\begin{align*}
\text{Bank} \\
\text{clients} : \text{UID} \rightarrow \text{NAME} \\
\text{balances} : \text{ACCNUM} \rightarrow \text{BALANCE} \\
\text{owners} : \text{UID} \leftrightarrow \text{ACCNUM} \\
\text{dom clients} = \text{dom owners} \\
\text{dom balances} = \text{ran owners} \\
\text{ran balances} \subseteq \mathbb{N}
\end{align*}
\]

instead of the one we have defined at the beginning of this section. Note that, in this way the state invariant is conjoined to the predicate part of every schema where \( \Delta \text{Bank} \) or \( \Xi \text{Bank} \) are included. This is a simple technique that guarantees that every operation will preserve the state invariant.

However, for reasons that we are going to explain in Section 3.6.4, we deal with state invariants in a different fashion. We first define a schema stating the invariant:

\[
\begin{align*}
\text{BankInv} \\
\text{Bank} \\
\text{dom clients} = \text{dom owners} \\
\text{dom balances} = \text{ran owners} \\
\text{ran balances} \subseteq \mathbb{N}
\end{align*}
\]
and then we require a proof obligation stating that each operation preserves it. For example:

**Theorem** \(\text{NewClientInv} \)

\[\text{BankInv} \land \text{NewClient} \Rightarrow \text{BankInv}'\]

Discharging such proof obligations is a responsibility of those who write the specification. This way of writing invariants is similar to other formal methods such as TLA+ [25] and B [1].

### 3 Introduction to the Test Template Framework

As we have said, the TTF is a particular method for the “Generation” step of the MBT process (Figure [2]), specially well suited for unit testing from Z specifications. Each operation within the specification is analysed to derive or generate abstract test cases. This analysis consists of the following steps:

1. Consider the VIS of each Z operation
2. Apply one or more testing tactics in order to partition the input space
3. Build a tree of test specifications
4. Prune inconsistent test specifications
5. Find one abstract test case from each remaining test specification

Before executing the first step, engineers have to select those schemas that are operations. In effect, not all schemas representing operations have to be selected because some of them are used in the definition of others. For example, in the specification of the savings account system \(\text{ClientAlreadyExists}\) and \(\text{AccountAlreadyExists}\), among others, will not be selected because by selecting \(\text{NewClient}\) test cases for them would also be generated.

#### 3.1 The Valid Input Space of a Z Operation

The VIS of a Z operation is derived from the its Input Space (IS). The IS of an operation is the schema declaring all the state and input variables declared in the operation. For example, the IS of \(\text{NewClient}\) is:

\[\text{NewClient}_{\text{IS}} \equiv\]

\[
\begin{align*}
\text{clients} & : \text{UID} \rightarrow \text{NAME}; \\
\text{owners} & : \text{UID} \leftrightarrow \text{ACCNUM}; \\
\text{balances} & : \text{ACCNUM} \rightarrow \text{BALANCE}; \\
\text{name} & : \text{NAME}; \\
\text{u} & : \text{UID}; \\
\text{n} & : \text{ACCNUM}
\end{align*}
\]

The VIS is the schema that restricts the IS to verify the precondition of the operation:

\[\text{Op}_{\text{VIS}} \equiv [\text{Op}_{\text{IS}}|\text{pre Op}]\]

Informally, the precondition of an operation is that part of its predicate that does not contain output nor primed-state variables. Z provides the \text{pre} operation which takes a schema and returns its precondition. The VIS of a total operation is equal to its IS, since, by definition, its precondition is equivalent to \(\text{true}\). \(\text{NewClient}\) is a total operation, therefore, we have:

\[\text{NewClient}_{\text{VIS}} \equiv \text{NewClient}_{\text{IS}}\]
3.2 Applying Testing Tactics

The key aspect of the TTF is to partition the VIS of each operation into equivalence classes by applying one or more testing tactics. These equivalence classes are called test classes, test objectives, test templates or test specifications; we will use the latter. In other words, a test specification $S$ of some operation $Op$ is a set such that $S \subseteq Op_{VIS}$. Test specifications obtained in this way can be further subdivided into more test specifications by applying other testing tactics. The net effect of this technique is a progressive partition of the VIS into more restrictive test specifications. This procedure can continue until the engineer is satisfied with the possible accuracy of the test specifications with respect to their ability to uncover errors in the implementation. Once the engineering is done with partitioning, she/he has to take one abstract test case from each resulting test specification.

Although, theoretically, testing tactics should produce a partition, in practice this is not always the case. Producing a partition is relevant because in some way it guarantees both full coverage of the VIS and non-repetition of test cases. Given a VIS $S$, a partition for $S$ is a family of test specifications $\{S_i\}_{i \in I}$ for some set of indexes $I$, such that:

\[
\bigcup_{i \in I} S_i = S \quad \text{(1)}
\]

\[
S_i \cap S_j = \emptyset \text{ for all } i, j \in I \text{ and } i \neq j \quad \text{(2)}
\]

Therefore, by taking an abstract test cases from every $S_i$, $S$ is fully covered and no two test cases test the same. On the contrary, if $\{S_i\}_{i \in I}$ is not a partition then either something is not tested or two or more test cases will test the same. In this sense, the TTF relies on the uniformity hypothesis [18], which can be stated as follows:

**Uniformity hypothesis.** Let $S_i$ be a test specification of some partition for some program $P$. Let $t_1$ and $t_2$ be two elements of $S_i$. The uniformity hypothesis says, then, that $P$ passes $t_1$ if and only if $P$ passes $t_2$.

In other words, the hypothesis says that each test specification is an equivalence class with respect to the way the program behaves for any element of it. Although this hypothesis cannot be proved many MBT methods rely on it [21]. From a safety perspective, if a testing tactic does not produce a partition of a test specification, then it should at least verify equation (1).

Therefore, testing tactics are the tools that testers have to partition the VIS of each operation. A tactic indicates how the current test specification must be partitioned by giving a set of predicates that are used to define each partition. Each of these predicates is called characteristic predicate; i.e. it characterizes a test specification. Each testing tactic partitions a test specification in a different way aiming at producing test cases to test different aspects of a program.

The original authors of the TTF proposed some testing tactics [36, 37] and we propose more (see Chapter ??). In this section we will apply two of the original tactics to the NewClient operation. The first one we will apply, called DNF, was proposed even before the TTF [14], and in general it does not produce a partition. It says:

1. Write the predicate of the operation in DNF.
   
   Writing a predicate in DNF means writing it as a disjunction of conjunctions of atomic predicates or negations of atomic predicates.

2. Take the precondition of each resulting disjunct.
\[ S = \emptyset, T = \emptyset \quad S \neq \emptyset, T \neq \emptyset, S \subseteq T \\
S = \emptyset, T \neq \emptyset \quad S \neq \emptyset, T \neq \emptyset, T \subseteq S \\
S \neq \emptyset, T = \emptyset \quad S \neq \emptyset, T \neq \emptyset, T = S \\
S \neq \emptyset, T \neq \emptyset, S \cap T = \emptyset \quad S \neq \emptyset, T \neq \emptyset, S \cap T \neq \emptyset, \neg (S \subseteq T), \\
\neg (T \subseteq S), S \neq T \\
\]

Figure 3: Standard partition for \( S \cup T, S \cap T \) and \( S \setminus T \)

3. Take these predicates as the characteristic predicates of the partition.

Let’s apply it on \( NewClient \) before explaining it informally. The first step, in this example, is easy because the operation is already in DNF. Then, we get the following test specifications:

\[
NewClient^{\text{DNF}}_1 == [\text{NewClient}_{\text{VIS}} | u? \not\in \text{dom clients} \land n? \not\in \text{dom balances}] \\
NewClient^{\text{DNF}}_2 == [\text{NewClient}_{\text{VIS}} | u? \in \text{dom clients}] \\
NewClient^{\text{DNF}}_3 == [\text{NewClient}_{\text{VIS}} | n? \in \text{dom balances}] \\
\]

First, note that test specifications are written in Z. This is a virtue of the TTF since it keeps all the main artifacts within the same notation. Second, note how test specifications are linked to the VIS by schema inclusion. Third, observe that this is not a partition of the VIS because, for example, the following abstract test case satisfies \( NewClient^{\text{DNF}}_2 \) and \( NewClient^{\text{DNF}}_3 \):

\[
\begin{align*}
\text{clients} &= \{ \text{uid0} \mapsto \text{name0} \}, \\
\text{balances} &= \{ \text{accnum0} \mapsto 1 \}, \\
\text{owners} &= \{ \text{uid0} \mapsto \text{name0} \}, \\
u? &= \text{uid0}, \\
n? &= \text{accnum0}
\end{align*}
\]

However, DNF is a very good tactic because it generates test specifications that will test the main functional alternatives of the implementation. Nevertheless, it does not produce test cases to test the implementation of complex mathematical operators, as noted Stocks and Carrington in their seminal papers. In effect, most likely a Z specification will have mathematical operators—such as \( \cup \) and \( \oplus \)—that do not have a basic representation in most programming languages; i.e. they need a non trivial implementation.

For this cases, the TTF proposes a powerful testing tactic called SP. This tactic is parametrized by a mathematical operator. Then, the characteristic predicates indicated by SP to partition a test specification depends on a mathematical operator. Figure 3 shows the characteristic predicates proposed for the standard partition of \( \cup, \cap \) or \( \setminus \). Note that other partitions can be proposed and used. For example, a partition containing only the first two characteristic predicates plus \( S \neq \emptyset, T \neq \emptyset \) is possible—although it will tend to uncover less errors than the one in Figure 3.

Hence, engineers must analyze the specification of an operation looking for mathematical operators that they think it is likely that will have a complex implementation that would lead to errors in the program. Then, they must propose a standard partition for them—if none has been defined or they think
the one defined does not suit their needs—or use an existing one. Finally, they have to partition one or
more of the current test specification by conjoining the characteristic predicates of the standard partition.
If the same mathematical operator appears more than once in the operation then they have to decide on
which expression they are going to apply the tactic. If they want to apply the tactic to another instance
of the operator or to other operators, this can be considered as the application of another tactic, so they
can repeat the process after applying the first SP.

We will apply SP to $\cup$ in $clients \cup \{u? \mapsto \text{name}?\}$ in order to partition just $NewClient_{1}^{\text{DNF}}$. That
is, we will not partition $NewClient_{2}^{\text{DNF}}$ and $NewClient_{3}^{\text{DNF}}$ by SP, because, in this case, we assess that
partitioning them in this way will not lead to a better coverage. This is so because if a test case meets
the conditions of $NewClient_{2}^{\text{DNF}}$ or $NewClient_{3}^{\text{DNF}}$, it will unlikely make the program to execute the code
where $\cup$ is implemented. Besides, in this first application of SP we will not produce test specifications
aimed at testing the correct implementation of $balances \cup \{n? \mapsto 0\}$ and $owners \cup \{u? \mapsto n?\}$. We will
not do that in this thesis to keep the example manageable, although in practice it should be done.

In summary, applying SP to $\cup$ in $clients \cup \{u? \mapsto \text{name}?\}$ to partition $NewClient_{1}^{\text{DNF}}$ yields the fol-
lowing new test specifications:

$$NewClient_{1}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients = \emptyset \land \{u? \mapsto \text{name}?\} = \emptyset]$$

$$NewClient_{2}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients = \emptyset \land \{u? \mapsto \text{name}?\} \neq \emptyset]$$

$$NewClient_{3}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients \neq \emptyset \land \{u? \mapsto \text{name}?\} = \emptyset]$$

$$NewClient_{4}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients \neq \emptyset \land \{u? \mapsto \text{name}?\} \neq \emptyset \land clients \cap \{u? \mapsto \text{name}?\} = \emptyset]$$

$$NewClient_{5}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients \neq \emptyset \land \{u? \mapsto \text{name}?\} \neq \emptyset \land clients \subset \{u? \mapsto \text{name}?\}]$$

$$NewClient_{6}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients \neq \emptyset \land \{u? \mapsto \text{name}?\} \neq \emptyset \land \{u? \mapsto \text{name}?\} \subset clients]$$

$$NewClient_{7}^{SP} =$$
$$[NewClient_{1}^{\text{DNF}}\mid clients \neq \emptyset \land \{u? \mapsto \text{name}?\} \neq \emptyset \land clients = \{u? \mapsto \text{name}?\}]$$
Note that, again, test specifications are linked to each other by schema inclusion. Also observe that applying SP is no more that substituting the “formal” operands appearing in the partition definition by the “real” operands appearing in the selected expression.

As we have said, we will stop applying testing tactics in this example to keep it small. However, in a real project some more testing tactics can and should be applied to this operation. We will show the application of other tactics to other operations of the savings accounts system in Chapter ??.

### 3.3 Building a Tree of Test Specifications

According to the TTF, the test specifications of a given operation must be organized in a so called testing tree. The testing tree has the VIS at the root, the test specifications generated after applying the first testing tactic form the first level and so forth. The testing tree of NewClient is shown in Figure 4(a).

Testing trees are important because the TTF prescribes deriving abstract test cases only from their leaves. This is so because each leaf conjoins the predicate of the test specifications above it up to the root, thus making no sense to derive abstract test cases from the internal nodes. For instance, if NewClient$_1^{DNF}$
is unfolded in $NewClient_{4}^{SP}$, the result is as follows:

$$NewClient_{4}^{SP} ==$$

\[ [NewClient_{VIS}] \]

\[ u? \notin \text{dom clients} \land n? \notin \text{dom balances} \land \text{clients} \neq \emptyset \land \{u? \mapsto \text{name}?\} \neq \emptyset \land \text{clients} \cap \{u? \mapsto \text{name}?\} = \emptyset \]

Therefore, a test case that satisfies $NewClient_{4}^{SP}$ will also satisfy $NewClient_{1}^{DNF}$.

These trees can be automatically obtained from the test specifications since children include a reference to their parent node by schema inclusion, as can be seen in the test specifications shown above.

3.4 Pruning Inconsistent Test Specifications

Some test specifications might be empty because their predicates are unsatisfiable. In these cases it is impossible to find abstract test cases. Hence, inconsistent test specifications must be pruned from the testing trees. For instance, $NewClient_{1}^{SP}$ is inconsistent because $\{u? \mapsto \text{name}?\}$ cannot be empty. Another example is $NewClient_{7}^{SP}$, because $\text{clients}$ cannot be equal to $\{u? \mapsto \text{name}?\}$ since $u? \notin \text{dom clients}$ also holds. In our example, the testing tree resulting after pruning is depicted in Figure 4[b].

3.5 Deriving Abstract Test Cases from Test Specifications

Finally, the engineer has to choose at least one element satisfying each of the remaining leaves of the testing tree. These are the abstract test cases. For example, the following horizontal schemas represent abstract test cases of the corresponding test specifications:

$$NewClient_{1}^{TC} ==$$

\[ [NewClient_{2}^{SP}] \]

\[ balances = \emptyset \land u? = uid0 \land \text{clients} = \emptyset \land n? = accnum0 \land \text{name}? = name0 \land \text{owners} = \emptyset \]
Note that, once more, abstract test cases are also written in Z and how they are linked to test specifications by schema inclusion.

Fastest eliminates unsatisfiable test specification and finds abstract test cases by using the \texttt{\{log\}} tool (pronounced ‘setlog’) \cite{31,13}. Both activities are almost automatic for users.

### 3.6 Brief Discussion of the TTF

We do not pretend here to compare the TTF with other approaches because it has been done when it was first published \cite{37} and more recently \cite{21}. We just want to highlight some issues that are related to the chances of automating it or issues that deviate from the mainstream MBT methods.

#### 3.6.1 Advantages of the TTF

We find the TTF particularly appealing for Z users since it keeps all the key elements—operations, test specifications, abstract test cases and others—within the Z notation. Besides, it naturally provides traceability between all these elements by using schema inclusion. Furthermore, users can define new testing tactics that best fit their needs when the standard ones fall short.

#### 3.6.2 The Form of Test Cases in the TTF

As can be seen, within the TTF an abstract test case is a conjunction of equalities between VIS variables and constant values, rather than a sequence of operations leading to the desired state, as is suggested by
other approaches [34, 4, 14]. These sequences are useful when the SUT has to be put in a particular state so a test case can be run from there. Since the TTF does not produce such sequences, we have proposed a method that does two things at the same time [12]: (a) refines a TTF abstract test case into an executable program; and (b) sets the initial state of the SUT according to the abstract test case. The only prerequisite is the availability of the source code of the SUT. However, we think that the presentation of this method is outside the scope of this thesis because it concentrates on the “Generation” step of Figure 2. By saying this we want to remark that not representing test cases as sequences of operations does not necessarily mean a weakness of the TTF, it only suggests that other approaches for the execution of test cases should be investigated.

3.6.3 Test Oracles in the TTF

We consider necessary to explain how the TTF deals with test oracles, since this is different from other MBT approaches. A test oracle is a means by which it is possible to determine whether a test case has found an error in the implementation or not. Two of the advantages of the MBT methods is that oracles are rather easy to generate and then, in turn, it allows to automatically determine the presence of an error. The TTF is no exception in this regard, although it deals with test oracles in a rather different way.

Given that the ultimate goal of test oracles is to determine the presence of an error, they are useful once the SUT has been executed on a test case. In other words, it is not mandatory to generate test oracles during the “Generation” step of Figure 2 as long as they are available when the final decision about the presence of an error has to be made. Precisely, test oracles in the TTF can be calculated when that decision is about to be made. Following Figure 2 within the TTF an abstract test case is refined or concretized to become a concrete test case on which the program can be exercised. When the program is executed on such a test case, it produces some concrete output (messages on the screen, return values, exceptions, files, etc.). However, since this output is not necessarily at the level of the specification, it cannot be compared to it. Therefore, the output is abstracted to the level of the specification. In doing so, each output and after-state variable is bound to a constant value as with abstract test cases. Once this process is finished, the abstract test case and the corresponding abstract output are substituted in the specification of the corresponding Z operation. This turns the predicate of the operation into a constant formula, since both abstract test cases and abstract outputs are constants. Therefore, these predicates can be symbolically evaluated. Clearly, if one of this predicates reduces to true no error was found—because the output produced by the program corresponds to the expected output for the input that was provided—; but if it reduces to false there is an error in the program.

Hence, in the TTF test cases do not include their oracles, as we have seen when the TTF was introduced. In fact, an abstract test case only defines the values for each input and state variable. Given that Fastest generates abstract test cases as prescribed in the TTF and that this thesis concerns only to the “Generation” step, the results of the case studies reported in this thesis do not include test oracles.

3.6.4 State Invariants in the TTF

As we have shown in Section 2.6 we prefer writing state invariants in a separated schema and not in the predicate part of the state schema. In this way, when the TTF is applied to an operation, state invariants are not considered. In other words, state invariants are not analysed in the process of test case generation. This would imply that the code implementing it will not be tested.

However, if our approach for recording state invariants is followed there should be a proof for each operation guaranteeing that the latter satisfies the former. This means that each operation was specified in
such a way as to verify the state invariant. Therefore, when the operation is analysed by the TTF, it will generate test cases that will test code implementing sufficient functionality to make the program verify the state invariant—because it implements its specification and the specification satisfies the invariant. More formally: if operation $O$ satisfies invariant $I$—i.e. $I \land O \Rightarrow I'$—and we “prove” by testing that program $P$ implements $O$—i.e. $P \Rightarrow O$—, then we can prove that $P$ satisfies $I$—i.e. $I \land P \Rightarrow I'$. In summary, there is no need in considering state invariants during the “Generation” step as long as the corresponding proof obligations have been discharged.

There is another reason for writing state invariants as proof obligations rather than as part of the state schema. If state invariants are written inside the state schema they tend to produce implicit preconditions [35, page 130] [24, Section 7.6]. That is, preconditions that are not explicitly written by the specifier but which are implicit in the specification. Making implicit preconditions explicit requires solving an existential quantification. Given that the first step of the TTF is to define the VIS of each operation, and this, in turn, is defined in terms of the preconditions of the operation, then we need a simple way of getting the preconditions of the operation. Therefore, if there are implicit preconditions it is not possible to guarantee always to find all the preconditions of a given operation—but only its explicit ones. If state invariants are written as proof obligations all the preconditions must be explicit and, thus, easy to find. Hence we advocate for writing state invariants as proof obligations.

Both the TTF and Fastest work fine with either form of writing state invariants. Nevertheless, both work better if our proposal is followed because including the state invariant in an operation makes it much complex but this complexity does not mean better testing, as we have analysed in the previous paragraphs.

4 The Z Specification of the Landing Gear System

4.1 Basic Types

The Z specification uses the following basic types with the meaning given below.

- $LSET ::= \text{forward}|\text{left}|\text{right}$
- $HPOS ::= \text{down}|\text{up}$
- $EVST ::= \text{pressing}|\text{idle}$
- $SENS ::= s1|s2|s3$
- $LIGHT ::= \text{on}|\text{off}$

The front gear of the aircraft $\approx \text{forward}$
The left gear of the aircraft $\approx \text{left}$
The right gear of the aircraft $\approx \text{right}$
The down position of the handle located in the cockpit $\approx \text{down}$
The up position of the handle located in the cockpit $\approx \text{up}$
An electro-valve is supplying hydraulic power $\approx \text{pressing}$
An electro-valve is not supplying hydraulic power $\approx \text{idle}$
The name “front” is already used in the Z mathematical toolkit so it cannot be used in type $LSET$. It has been replaced by $\textit{forward}$.

Observe that elements of $SENS$ are regarded as identifiers; they are not the actual sensors which are not represented in this model. In this model when a device reads from its sensors it receives three ordered pairs of the form $(\textit{sensor\_id}, \textit{value})$. Hence, all the devices use the same set of sensor identifiers.

The elements of type $ST$ have different meanings depending on to which variable are bound.

$$ST ::= y|n$$

When $ST$ is used for:
- gears then $y$ means locked and $n$ means maneuvering
- door opening then $y$ means open and $n$ means not open
- door closing then $y$ means closed (and locked) and $n$ means not closed (and not locked)
- the hydraulic circuit (after the general electro-valve) then $y$ means pressurized and $n$ means not pressurized
- shock absorbers then $y$ means ground and $n$ means flight (or relaxed)
- the analogical switch then $y$ means closed and $n$ means open

During the execution of the expected scenarios in normal mode (i.e. outgoing and retraction sequences) the controlling software passes through some internal states which are represented by type $STATE$. The meaning of each state will become clear with the specification of these scenarios. States $d0, \ldots, d7$ concern the outgoing sequence, and states $u0, \ldots, u7$ the retraction sequence.

$$STATE ::= \textit{init}|d0|d1|d2|d3|d4|d5|d6|d7|u0|u1|u2|u3|u4|u5|u6|u7$$

In this model the time is discrete and starts from zero.

$$TIME == \mathbb{N}$$

### 4.2 State of the Controlling Software

The state of the software is given by means of several state variables grouped in some state schemas as described below. The grouping of state variables in different schemas allows operations schemas to use (access) the minimum number of variables they need. This, in turn, make it simpler test case generation.

The first state schema groups the variables that set the state of the gears of the aircraft. It includes the following variables:

- The gear $g$ is locked or not locked in extended position $\approx g\textit{Ext\,}g$
- The gear $g$ is locked or not locked in retracted position $\approx g\textit{Rec\,}g$
- The valid sensors sensing whether gear $g$ is locked or not locked in extended position $\approx sG\textit{Ext\,}g$
- The valid sensors sensing whether gear $g$ is locked or not locked in retracted position $\approx sG\textit{Rec\,}g$
Since the type of \( g_{Ext} \) and \( g_{Rec} \) is defined in terms of type \( ST \) and given that these variables represent properties of the gears, then the \( y \) value of \( ST \) means locked while the \( n \) value means maneuvering. Recall the list of interpretations for \( ST \) given in page \[21\].

According to this, if, for instance, at time \( t \) the sensors sensing whether the front gear is locked or not locked in extended position deliver the following values:

\[
s_1 \mapsto y, s_2 \mapsto n, s_3 \mapsto y
\]

then at time \( t \) the value of \( sG_{Ext\: front} \) will be \( \{s_1, s_3\} \). The same applies to \( sG_{Rec} \) and in general to all the variables that represent the set of valid sensors of the various devices of the LGS.

\[
\begin{align*}
Gears_{Extending} & \quad g_{Ext} : LSET \rightarrow ST \\
s_{GExt} : LSET \rightarrow FSENS
\end{align*}
\]

\[
\begin{align*}
Gears_{Retracting} & \quad g_{Rec} : LSET \rightarrow ST \\
s_{GRec} : LSET \rightarrow FSENS
\end{align*}
\]

\[
Gears \equiv Gears_{Extending} \land Gears_{Retracting}
\]

\( g_{Ext} \) could be defined also as of type \( F\: LSET \), which would be closer to the Z style. In this way, \( g \in g_{Ext} \) if and only if gear \( g \) is locked in extended position. However, in this particular model it seems easier (and clearer) to define \( g_{Ext} \) as a function. The same applies to \( g_{Rec} \).

State schema \( Doors \) plays the same role for doors than \( Gears \) for gears with a similar set of state variables. Therefore, only its designations are given below. Recall the list of interpretations for \( ST \) given in page \[21\].

\[
\begin{align*}
Doors_{Opening} & \quad d_{Op} : LSET \rightarrow ST \\
s_{DOp} : LSET \rightarrow FSENS
\end{align*}
\]

\[
\begin{align*}
Doors_{Closing} & \quad d_{Cl} : LSET \rightarrow ST \\
s_{DCl} : LSET \rightarrow FSENS
\end{align*}
\]

\[
Doors \equiv Doors_{Opening} \land Doors_{Closing}
\]

The door \( d \) is in open or not open position \( \approx d_{Op} \; d \)

The door \( d \) is locked or not locked in closed position \( \approx d_{Cl} \; d \)

The valid sensors sensing whether door \( d \) is in open or not open position \( \approx s_{DOp} \; d \)

The valid sensors sensing whether door \( d \) is locked or not locked in closed position \( \approx s_{DCl} \; d \)
The following schema groups the variables for the shock absorbers. They are quite similar to those of the preceding schemas. So, only its designations are given. Recall the list of interpretations for \( ST \) given in page \[21\]

\[
\begin{align*}
\text{ShockAbsorbers} \\
\text{(sa : LSET} \rightarrow \text{ST)} \\
\text{(sSA : LSET} \rightarrow \text{SENS)}
\end{align*}
\]

The shock absorber \( s \) is in ground or in flight position \( \approx sas \)

The valid sensors sensing whether shock absorber \( s \) is in ground or in flight position \( \approx sSAs \)

Given that there is only one hydraulic circuit dedicated to the LGS it is not necessary to define a function to record its state; one simple variable is enough. Then, \( hc \) stores the state of the hydraulic circuit. Recall the list of interpretations for \( ST \) given in page \[21\]

\[
\begin{align*}
\text{HydraulicCircuit} \\
\text{(hc : ST)} \\
\text{(sHC : SENS)}
\end{align*}
\]

The hydraulic circuit is pressurized or not pressurized \( \approx hc \)

The valid sensors sensing whether the hydraulic circuit is pressurized or not pressurized \( \approx sHC \)

The following schema look like \textit{HydraulicCircuit} so only its designations are given.

\[
\begin{align*}
\text{AnalogicalSwitch} \\
\text{(as : ST)} \\
\text{(sAS : SENS)}
\end{align*}
\]

The analogical switch is open or closed \( \approx as \)

The valid sensors sensing whether the analogical switch is open or closed \( \approx sAS \)

\textit{Handle} groups the state variables regarding the handle in the cockpit. It includes the position of the handle \( (hPos) \) and two time marks necessary for the timing constraints.

\[
\begin{align*}
\text{Handle} \\
\text{(hPos : HPOS)} \\
\text{(lHPCh, l20 : TIME)}
\end{align*}
\]
The handle is up or down \( \approx hPos \)
Last time the handle position changed \( \approx lHPC\)h
Last time that the handle position has not changed for 20 seconds \( \approx l20 \)

Now follows some schemas grouping state variables of the different electro-valves. Each schema includes a variable to record the state of the corresponding electro-valve as well as one variable to store the last time the electro-valve was stimulated; only the general electro-valve has an extra variable to store the last time an electro-valve was stopped.

### GeneralEV

\[
\begin{align*}
\text{GeneralEV} & \quad \\
\text{stGEV, spGEV : TIME} & \\
gEV : EVST &
\end{align*}
\]

The general electro-valve is pressing (i.e. is providing hydraulic power) or is idle (i.e. is not providing hydraulic power) \( \approx gEV \)
Stimulation of the general electro-valve was started at time \( \approx stEV \)
Stimulation of the general electro-valve was stopped at time \( \approx spEV \)

### DoorOpeningEV

\[
\begin{align*}
\text{DoorOpeningEV} & \quad \\
doEV : EVST & \\
stDOEV : TIME &
\end{align*}
\]

The electro-valve related to door opening is pressing or is idle \( \approx doEV \)
Stimulation of the electro-valve related to door opening was started at time \( \approx stDOEV \)

### DoorClosingEV

\[
\begin{align*}
\text{DoorClosingEV} & \quad \\
dcEV : EVST & \\
stDCEV : TIME &
\end{align*}
\]

The electro-valve related to door closing is pressing or is idle \( \approx dcEV \)
Stimulation of the electro-valve related to door closing was started at time \( \approx stDCEV \)

### GearsExtendingEV

\[
\begin{align*}
\text{GearsExtendingEV} & \quad \\
geEV : EVST & \\
stGEEV : TIME &
\end{align*}
\]
The electro-valve related to gear extension is pressing or is idle $\approx geEV$

Stimulation of the electro-valve related to gear extension was started at time $\approx stGEEV$

$$GearsRetractingEV$$

$grEV : EVST$

$stGREV : TIME$

The electro-valve related to gear retraction is pressing or is idle $\approx grEV$

Stimulation of the electro-valve related to gear retraction was started at time $\approx stGREV$

There are two more variables to record time marks.

$$EVst$$

$stEV : TIME$

$$EVsp$$

$spEV : TIME$

Stimulation of an electro-valve was started at time $\approx stEV$

Stimulation of an electro-valve was stopped at time $\approx spEV$

Every time the general electro-valve is stimulated two variables will be updated:

- $gEV$ will be set to *pressing*; and
- $stGEV$ will be set to the current time

Every time the general electro-valve is stopped two variables will be updated:

- $gEV$ will be set to *idle*; and
- $spGEV$ will be set to the current time

Every time an electro valve is stimulated three variables will be updated. For example, if the door opening electro-valve is stimulated:

- $doEV$ will be set to *pressing*;
- $stDOEV$ will be set to the current time; and
- $stEV$ (from schema $EVst$) will be set to the current time

Every time an electro valve is stopped two variables will be updated. For example, if the door opening electro-valve is stimulated:

- $doEV$ will be set to *idle*;
- $spEV$ (from schema $EVsp$) will be set to the current time
In this way, it is possible to know:

- The elapsed time between two consecutive stimulations of any two electro-valves, through variable \( stEV \).
- The elapsed time between two consecutive orders to stop the stimulation of any two electro-valves, through variable \( spEV \).
- The elapsed time between two consecutive contrary orders of any two electro-valves, through variables \( stEV \), \( stDOEV \), \( stDCEV \), \( stGEEV \) and \( stGREV \).
- The last time the general electro-valve was stimulated or stopped, through variables \( stGEV \) and \( spGEV \).

The state of the cockpit is represented by three simple variables each of them corresponding to the three lights that inform the pilot about the state of the LGS. The “landing gear system failure” light \( lgsfl \) is used as a synonym for “LGS mode of operation”. That is when \( lgsfl = \text{on} \) the LGS has failed and the pilot can activate the emergency hydraulic circuit; when \( lgsfl = \text{off} \) the LGS is operating normally.

\[
\begin{align*}
\text{CockpitA} & \quad lgsfl : \text{LIGHT} \\
\text{CockpitN} & \quad gldl, gml : \text{LIGHT}
\end{align*}
\]

\( \text{Cockpit} = = \text{CockpitA} \land \text{CockpitN} \)

The “landing gear system failure” light \( \approx lgsfl \)

The “gears are locked down” light \( \approx gldl \)

The “gears maneuvering” light \( \approx gml \)

When the two main scenarios in normal mode (i.e. the outgoing and retraction sequences) are executed the software goes through a series of internal states. The following variable records that state.

\[
\begin{align*}
\text{StateCounter} & \quad st : \text{STATE} \\
\end{align*}
\]

The software internal state during either the outgoing or retraction sequence \( \approx st \)

Since there are several timing restrictions that the software must meet, the model keeps track of time advance by means of variable \( now \). This variable is incremented by 1 ms.

\[
\begin{align*}
\text{Time} & \\
now : \text{TIME}
\end{align*}
\]
The current time \( \approx \text{now} \)

### 4.3 Initial states

The initial state of the system represents a “healthy” aircraft on ground. That is, its gears are locked down (which in turn means that they are not retracted), the doors are closed, all the sensors are operating correctly, etc. This state is set by setting the variables in each and every one of the state schemas defined above.

<table>
<thead>
<tr>
<th>( GearsInit )</th>
<th>( Gears )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( ran_g_Ext = {y} )</td>
<td></td>

```

The lights in the cockpit reflects the state of the gears and the healthy of the system.
The internal state counter is in its initial state.

The LGS time starts at zero.

4.4 Assumptions and Limitations of the Z Specification

The Z specification presented here (and the complete model described in [10]) is based on the following assumptions and limitations:

- Each Z operation is atomic and takes no time to be executed.
- If at a given point in time there is more than one operation enabled (i.e. their preconditions are true), the system nondeterministically executes one of them.
- Only one operation is executed at any given time.
- All operations are executed according to a weak fairness formula [25]. Z should be extended as Evans suggests to be able to write these formulas [16].
- The software stops working when the red light in the cockpit is turned on ($lgsfl = \text{on}$). Then, operations do not include the precondition $lgsfl = \text{off}$ because when this is no longer true the software is not working.
- The system measures the time in milliseconds; the time is considered to be discrete.
- The specification considers just one computing module [6 Sect. 2.3]. That is all the outputs produced by the software are produced by only one computing module.
- The sentence:
  
  two contrary orders (closure / opening doors, extension / retraction gears) must be separated by at least 100ms.

is interpreted as follows:

the start of stimulation of the electro-valves corresponding to devices that execute contrary orders must be separated by at least 100ms.
4.5 Operations Concerning Sensor Readings and its Anomalies

In this section the operations describing how the values read by sensors are stored in the system are formalized. These operations include the specification of the conditions under which an anomaly concerning the validity of sensors is detected.

Given that every device (gears, doors, shock absorbers, etc.) reads (simultaneously) from three sensors, the following operations take an input variable \( v \) of type \( SENS \rightarrow ST \). Its interpretation is simple: if \( s : SENS \) then \( v \triangleright s \) is the value delivered by sensor \( s \) at that moment. In this sense, \( v \) can be seen as the result of an election where each sensor votes for one of two possible candidates.

There are two key operations regarding \( v \) when a device of the LGS reads its sensors. The first one is to find the set of valid sensors. This set is formed by the majority who won the election. The \( y \) value won the election if \( \#(v \triangleright \{ y \}) > \#(v \triangleright \{ n \}) \), otherwise the winner is \( n \). Note that if \( \#v = 2 \) and each sensor reads a different value, \( n \) wins but this is irrelevant as is going to be shown below. The next function, \( valid \), calculates the set of valid sensors by taking the domain of \( v \triangleright \{ y \} \) or \( v \triangleright \{ n \} \) depending on who won the election.

\[
valid : (SENS \rightarrow ST) \rightarrow \exists SENS
\]
\[
\forall v : SENS \rightarrow ST \bullet
\]
\[
valid \, v =
\]
\[
\text{if } \#(v \triangleright \{ y \}) > \#(v \triangleright \{ n \}) \text{ then } \text{dom}(v \triangleright \{ y \})
\]
\[
\text{else } \text{dom}(v \triangleright \{ n \})
\]

Note that, although \( v \) is a total function, \( valid \) waits a partial function. This is so because when a sensor is invalidated the following readings consider only the two remaining sensors. Therefore, \( valid \) is called with \( v \) restricted to the two active sensors and this is a partial function.

The second operation regarding \( v \) is to determine the net value read by the three sensors. According to [6], the net value is the value read by the majority. \( value \), returns the net value in a similar way as \( valid \) returns the set of valid sensors.

\[
value : (SENS \rightarrow ST) \rightarrow ST
\]
\[
\forall v : SENS \rightarrow ST \bullet
\]
\[
value \, v =
\]
\[
\text{if } \#(v \triangleright \{ y \}) > \#(v \triangleright \{ n \}) \text{ then } y \text{ else } n
\]

Each of the following Z operations describe how a device of the LGS reads from its sensors and what the software does with these values. All these operations share a common structure:

- A first schema, whose name ends in \( N \), describing the case when the three sensors return the same value. \( N \) here suggests normal functioning.
- A second schema, whose name ends in \( Ds \), describing the case when a sensor returns a different value for the first time (and so it is discharged for ever). \( Ds \) here suggests degrades.
- A third schema, whose name ends in \( Dd \), describing the case when two sensors are working correctly. \( Dd \) here suggests degraded.
- A fourth schema, whose name ends in \( A \), describing the case when the two remaining sensors differ in their readings for the first time (and so a system anomaly is detected). \( A \) here suggests anomaly.
• A fifth schema as the disjunction of the four previous schemas that describes the full operation.

Since all the operations share a common structure and the predicates in them are very similar to each other, only the first operation is explained in detail.

4.5.1 Gears in Extended Position

The next five schemas describe the system reading the sensors that determine whether the gears are locked or not locked in extended position. Each schema receives the gear or landing set to which the reading applies, $g$?, and $v$? (as mentioned above). $\text{ReadGearsExtendingN}$ has only one preconditions: all the three sensors are valid with respect to reading $v$?. In other words this device is working in normal mode. Then, the state of the corresponding gear ($g$?) is updated according to the net value ($\text{value}(v)$) read by the sensors. The set of valid sensors of these devices ($sGExt$) remain unchanged (recall that the initial value for all the variables representing valid sets of sensors is $\text{SENS}$, see Sect. 4.3).

\[
\begin{align*}
\text{ReadGearsExtendingN} \\
\Delta \text{GearsExtending}; \Xi \text{CockpitA} \\
g? : \text{LSET} \\
v? : \text{SENS} \rightarrow \text{ST} \\
\text{valid}(v) = \text{SENS} \\
gExt' = gExt \oplus \{g? \mapsto \text{value}(v)\} \\
sGExt' = sGExt
\end{align*}
\]

In $\text{ReadGearsExtendingDs}$ the device for $g$ starts to work in degraded mode because one of the sensors reads a different value with respect to the other two ($\text{valid}(v) \subset \text{SENS}$), when previously all of them were working properly ($sGExt g = \text{SENS}$). Therefore, the state of the corresponding gear ($g$?) is updated according to the net value ($\text{value}(v)$) read by the sensors and the set of valid sensors for $g$ is also updated.

\[
\begin{align*}
\text{ReadGearsExtendingDs} \\
\Delta \text{GearsExtending}; \Xi \text{CockpitA} \\
g? : \text{LSET} \\
v? : \text{SENS} \rightarrow \text{ST} \\
\text{valid}(v) \subset \text{SENS} \\
gExt' = gExt \oplus \{g? \mapsto \text{value}(v)\} \\
sGExt' = sGExt \oplus \{g? \mapsto \text{valid}(v)\}
\end{align*}
\]

Now that there are just two valid sensors the net value must be calculated from them. So $\text{ReadGearsExtendingDd}$ is applied if the set of valid sensors is strictly included in $\text{SENS}$ and it is exactly the same set recorded by the system: $\text{valid}(sGExt g \triangleleft v) = sGExt g$. In other words, since one of the sensors is no longer considered (although it keeps sending its readings to the system), the set of valid sensors is calculated from the set of sensors that are currently considered valid: $sGExt g$. So $\text{valid}$ is called with $v$ restricted to the set of valid sensors ($sGExt g \triangleleft v$) to see if this is still the same set. The same applies to the way the net value is calculated: $\text{value}(sGExt g \triangleleft v)$. 
Z Specification of the Landing Gear System

**ReadGearsExtendingDd**

$$\Delta \text{GearsExtending}; \exists \text{CockpitA}$$

$$g? : \text{LSET}$$

$$v? : \text{SENS} \rightarrow \text{ST}$$

$$sGExt g? \subseteq \text{SENS}$$

$$\text{valid}(sGExt g? \triangleright v?) = sGExt g?$$

$$gExt' = gExt \oplus \{g? \mapsto \text{value}(sGExt g? \triangleright v?)\}$$

$$sGExt' = sGExt$$

If one of the two working sensors fails ($$\text{valid}(sGExt g? \triangleright v?) \neq sGExt g?$$) then the system moves to a failed state by turning on the read light in the cockpit: $$\text{lgsf}l' = \text{on}$$. Remember that it was assumed that from this moment the software is not working anymore. By the way, note that in this case $$\text{valid}$$ will arbitrarily return the set $$\{s_i\}$$ where $$v?s_i = n$$. However, this is irrelevant because this set will be different from $$sGExt g?$$ since it has two elements.

**ReadGearsExtendingA**

$$\exists \text{GearsExtending}; \Delta \text{CockpitA}$$

$$g? : \text{LSET}$$

$$v? : \text{SENS} \rightarrow \text{ST}$$

$$sGExt g? \subseteq \text{SENS}$$

$$\text{valid}(sGExt g? \triangleright v?) \neq sGExt g?$$

$$\text{lgsf}l' = \text{on}$$

**ReadGearsExtending** is simply the disjunction of the preceding four schemas, thus defining the full operation of reading the sensors informing about the lock of gears in extended position.

$$\text{ReadGearsExtending} == \text{ReadGearsExtendingN} \lor \text{ReadGearsExtendingDs} \lor \text{ReadGearsExtendingDd} \lor \text{ReadGearsExtendingA}$$

As has been said above, the next schemas share the same structure and have similar predicates so no more informal explanations will be given.

### 4.5.2 Gears in Retracted Position

The system reads the sensors indicating whether the gears are locked or not locked in retracted position $$\approx \text{ReadGearsRetracting}$$

**ReadGearsRetractingN**

$$\Delta \text{GearsRetracting}; \exists \text{CockpitA}$$

$$g? : \text{LSET}$$

$$v? : \text{SENS} \rightarrow \text{ST}$$

$$\text{valid}(v?) = \text{SENS}$$

$$gRec' = gRec \oplus \{g? \mapsto \text{value}(v?)\}$$

$$sGRec' = sGRec$$
4.5.3 Shock Absorbers

The system reads the sensors indicating whether the shock absorbers are on ground or in flight \( \approx \text{ReadShockAbsorbers} \)
4.5.4 Doors Open

The system reads the sensors indicating whether the doors are in open or not open position.

\[ \approx \text{ReadDoorsOpening} \]

\[ \text{ReadDoorsOpeningN} \]
\[ \Delta \text{DoorsOpening}; \Xi \text{CockpitA} \]
\[ g? : \text{LSET} \]
\[ v? : \text{SENS} \rightarrow \text{ST} \]
\[ \text{valid}(v?) = \text{SENS} \]
\[ \text{dOp}' = \text{dOp} \oplus \{ g? \mapsto \text{value}(v?) \} \]
\[ \text{sDOp}' = \text{sDOp} \]
4.5.5 Doors Closed

The system reads the sensors indicating whether the doors are locked or not locked in closed position \( \approx \) \textit{ReadDoorsClosing}
**ReadDoorsClosingDs**

\[ \Delta \text{DoorsClosing}; \Xi \text{CockpitA} \]
\[ g? : \text{LSET} \]
\[ v? : \text{SENS} \rightarrow \text{ST} \]
\[ sDCl g? = \text{SENS} \]
\[ \text{valid}(v?) \subseteq \text{SENS} \]
\[ dCl' = dCl \oplus \{g? \mapsto \text{value}(v?)\} \]
\[ sDCl' = sDCl \oplus \{g? \mapsto \text{valid}(v?)\} \]

**ReadDoorsClosingDd**

\[ \Delta \text{DoorsClosing}; \Xi \text{CockpitA} \]
\[ g? : \text{LSET} \]
\[ v? : \text{SENS} \rightarrow \text{ST} \]
\[ sDCl g? \subseteq \text{SENS} \]
\[ \text{valid}(sDCl g? \triangleleft v?) = sDCl g? \]
\[ dCl' = dCl \oplus \{g? \mapsto \text{value}(sDCl g? \triangleleft v?)\} \]
\[ sDCl' = sDCl \]

**ReadDoorsClosingA**

\[ \Xi \text{DoorsClosing}; \Delta \text{CockpitA} \]
\[ g? : \text{LSET} \]
\[ v? : \text{SENS} \rightarrow \text{ST} \]
\[ sDCl g? \subseteq \text{SENS} \]
\[ \text{valid}(sDCl g? \triangleleft v?) \neq sDCl g? \]
\[ lgsfl' = \text{on} \]

**ReadDoorsClosing**

\[ \text{ReadDoorsClosing} \rightleftharpoons \]
\[ \text{ReadDoorsClosingN} \lor \text{ReadDoorsClosingDs} \lor \text{ReadDoorsClosingDd} \lor \text{ReadDoorsClosingA} \]

### 4.5.6 Hydraulic Circuit

The remaining two operations describe the reading of single devices (hydraulic circuit and analogical switch). Then, the parameter \( g? \) used in the previous schemas is no longer needed. Furthermore, the predicates in these operations are simpler because the variables recording the state of the device and the set of valid sensors are plain variables (i.e. they are not functions as in the previous operations).

The system reads the sensors indicating whether the hydraulic circuit is pressurized or not pressurized \( \approx \text{ReadHydraulicCircuit} \)
4.5.7 Analogical Switch

The system reads the sensors indicating whether the analogical switch (between the digital part and the general electro-valve) is closed or open ≈ ReadAnalogicalSwitch
4.6 Operations Concerning Normal Mode

This section includes the Z operations that describe the interaction with the cockpit, the two main scenarios in normal mode (i.e. the outgoing and retracting sequences) and the counter orders that may be given during the execution of these scenarios.
The first operation represents the pilot moving the handle up or down. Each of these operations enables the corresponding main scenario.

Each of the two main scenarios is organized in eight schemas, each representing one of the steps or elementary actions described in [6, pages 14 and 15]. The third step of the retraction sequence is decomposed in two schemas.

The counter orders are decomposed in seven schemas each, because it has been considered that if the counter order arrives before the first step of the main scenario has been executed there is nothing to revert.

4.6.1 Interaction with the cockpit

In the initial state of the LGS the internal state counter, $st$, is equal to $init$; the handle, $hPos$, is in the down position; and the gears are locked in extended position (see Sect. 4.3). Then, the only thing the pilot can do is to move the handle to the up position. In this moment $st$ is set to the first internal state, $u0$, of the retracting sequence. This new value for $st$ enables the first step, $Up1$, of the retracting sequence. Besides, a time mark is taken when the pilot moves the handle to record the time of its last change: $lHPCh' = now$. All this is specified in $ChangeHandleDownUp$.

\[
\begin{align*}
\Delta Handle; \Delta StateCounter; \Xi Time \\
\ hPos = \text{down} \\
\ hPos' = \text{up} \\
\ lHPCh' = \text{now} \\
\ st' = u0 \\
\ l20' = l20
\end{align*}
\]

The symmetric operation is specified in $ChangeHandleUpDown$.

\[
\begin{align*}
\Delta Handle; \Delta StateCounter; \Xi Time \\
\ hPos = \text{up} \\
\ hPos' = \text{down} \\
\ lHPCh' = \text{now} \\
\ st' = d0 \\
\ l20' = l20
\end{align*}
\]

The complete specification is as follows:

$ChangeHandle == \ ChangeHandleDownUp \lor \ ChangeHandleUpDown$

Since anomalies are calculated in sections 4.5 and 4.8 this section includes only the interaction with the cockpit in normal mode. These interactions include turning on and off the lights indicating the position of gears. The first operation describes the conditions to turn on and off the green light which, when on, indicates that all the gears are locked down. The three gears are locked in extended position when $y$ is the only element of the range of $gExt$. In other words, when $gExt$ is applied to any element of $LSET$ the result is $y$, which means that each and every gear is locked in the extended position.
GearsLockedDownOn
\[ \Delta \text{CockpitN}; \Xi \text{GearsExtending} \]
\[ \text{ran gExt} = \{y\} \]
\[ \text{gldl}' = \text{on} \]

GearsLockedDownOff
\[ \Delta \text{CockpitN}; \Xi \text{GearsExtending} \]
\[ \text{ran gExt} \neq \{y\} \]
\[ \text{gldl}' = \text{off} \]

\[ \text{GearsLockedDown} = \text{GearsLockedDownOn} \lor \text{GearsLockedDownOff} \]

The second operation describes the conditions to turn on and off the orange light which, when on, indicates that gears are maneuvering. Note that “gears are not maneuvering” is formalized as:
\[ (\text{ran gExt} = \{y\} \lor \text{ran gRec} = \{y\}) \land \text{ran dCl} = \{y\} \]
so the negation of this predicate means “gears are maneuvering”:
\[ \neg ((\text{ran gExt} = \{y\} \lor \text{ran gRec} = \{y\}) \land \text{ran dCl} = \{y\}) \]
\[ \equiv (\text{ran gExt} \neq \{y\} \land \text{ran gRec} \neq \{y\}) \lor \text{ran dCl} \neq \{y\} \]
Therefore the operation is defined as follows:

GearsManeuveringOn
\[ \Delta \text{CockpitN}; \Xi \text{Gears}; \Xi \text{DoorsClosing} \]
\[ (\text{ran gExt} \neq \{y\} \land \text{ran gRec} \neq \{y\}) \lor \text{ran dCl} \neq \{y\} \]
\[ \text{gml}' = \text{on} \]

GearsManeuveringOff
\[ \Delta \text{CockpitN}; \Xi \text{Gears}; \Xi \text{DoorsClosing} \]
\[ (\text{ran gExt} = \{y\} \lor \text{ran gRec} = \{y\}) \land \text{ran dCl} = \{y\} \]
\[ \text{gml}' = \text{off} \]

\[ \text{GearsManeuvering} = \text{GearsManeuveringOn} \lor \text{GearsManeuveringOff} \]

4.6.2 Retraction sequence

When the handle is moved to the up position the internal state of the software, \( st \), is set to \( u0 \) which enables the first step of the retraction sequence formalized as follows:
As can be seen, Up1 has three preconditions:

- The internal state is \( u_0 \);
- The handle is in the \( up \) position; and
- The last time an electro-valve was stimulated was more than 200 ms before the current time or it is the first time an electro-valve is stimulated.

In turn its postconditions are simply:

- The general electro-valve is stimulated;
- The current time is saved in a state variable because later will be necessary to see if timing constraints regarding electro-valve stimulation are met; and
- The internal state is set to \( u_1 \).

A full specification of \( Up1 \) must say what the software should do if \( st = u_0 \land hPos = up \land (200 \leq now - stEV \lor stEV = 0) \) is not true. Although this seems odd, the software may fail and try to call the routine implementing \( Up1 \) when the system is in an unexpected state. In this case the system must remain in the same state. Then, the following schema is defined:

\[
Up1 = Up1Ok \lor Up1E
\]

Hence, the full operation is:

\[
Up1 == Up1Ok \lor Up1E
\]

In \( Up2 \) the door opening electro-valve is stimulated, then it is necessary to check whether enough time (100 ms) has elapsed since the last stimulation of the opposite electro-valve (door closing) unless the latter was never stimulated.
Besides, after Up1 has finished it is possible to receive a contrary order before any of the remaining step starts. Therefore, if a contrary order arrives between the moment that Up1 has just finished and right before Up2 starts, then the latter will stop the retraction sequence and will set the state of the system in such a way as to start the outgoing sequence at the right point. This is formalized as follows:

\[ \text{Up2Ok} \]
\[ \Delta \text{DoorOpeningEV}; \Delta \text{EVst}; \Delta \text{StateCounter} \]
\[ \Xi \text{DoorClosingEV}; \Xi \text{Time}; \Xi \text{Handle} \]

\[ st = u1 \]
\[ hPos = up \]
\[ 200 \leq now - stEV \]
\[ 100 \leq now - stDCEV \lor stDCEV = 0 \]
\[ doEV' = \text{pressing} \]
\[ stDOEV' = now \]
\[ stEV' = now \]
\[ st' = u2 \]

As can be seen Up2Ok has two preconditions:

- The handle is down; and
- \( st \) is in \( u1 \)

In this way, every time Up1 “finishes”, Up2Ok and UpDown2 can be enabled. However, in a given execution there will be just one of them enabled depending on whether the pilot has moved the handle or not in the meanwhile. In effect, if the pilot does not move the handle to the down position right after Up1, Up2Ok will be enabled, but if he or she moves the handle, then UpDown2 will be enabled. Note that when the handle is moved none of the Down schemas (see Sect. 4.6.3) become automatically enabled because they have as a precondition \( st = di \) with \( di \in \{d0, \ldots, d7\} \), and at this moment \( st \) is equal to \( u1 \) since the retracting sequence is being executed.

In summary, the following sequences of schema activations can take place when the handle is moved (this is just an informal presentation):

- \( \text{Up1Ok} \rightarrow \text{Up2Ok} \)
- \( \text{Up1Ok} \rightarrow \text{ChangeHandleUpDown} \rightarrow \text{UpDown2} \rightarrow \text{Down2} \)

The following schemas complete the specification of this step of the retraction sequence. Note that Up2E, unlike Up1E, does not include the negation of \( hPos = up \) because this is considered in UpDown2.

\[ \text{Up2E} \]
\[ \Xi \text{DoorOpeningEV}; \Xi \text{EVst}; \Xi \text{StateCounter}; \Xi \text{DoorClosingEV}; \Xi \text{Time}; \Xi \text{Handle} \]
\[ \neg (st = u1 \land 200 \leq now - stEV \land (100 \leq now - stDCEV \lor stDCEV = 0)) \]
\(Up2 == Up2Ok \lor UpDown2 \lor Up2E\)

The remaining schemas (\(Up3, \ldots, Up8\) as well as those of the outgoing sequence) are rather similar to \(Up2\). Hence, only minimal explanations are given.

\(Up31\) deals with the part of step 3 when the shock absorbers are in flight (relaxed). In this case the gear retraction electro-valve is stimulated. This schema adds two preconditions:

- All the doors are already opened (\(\text{ranOp} = \{y\}\)); and
- All the shock absorbers are in flight (\(\text{ran}\text{sa} = \{n\}\)).

\[
\begin{align*}
&\Delta \text{GearsRetractingEV}; \Delta \text{EVst}; \Delta \text{StateCounter} \\
&\Xi \text{GearsExtendingEV}; \Xi \text{DoorsOpening}; \Xi \text{ShockAbsorbers}; \Xi \text{Time}; \Xi \text{Handle} \\
&st = u2 \\
&hPos = up \\
&\text{ranOp} = \{y\} \\
&\text{ran}\text{sa} = \{n\} \\
&200 \leq now - stEV \\
&100 \leq now - st\text{GEEV} \lor st\text{GEEV} = 0 \\
&\text{grEV}' = \text{pressing} \\
&st\text{GREV}' = now \\
&stEV'' = now \\
&st' = u3
\end{align*}
\]

\(Up32\) deals with the opposite case: one or more shock absorbers are not seen as in flight (\(\text{ran}\text{sa} \neq \{n\}\)). In this case nothing is done except advancing the internal state to \(u4\).

\[
\begin{align*}
&\Delta \text{StateCounter} \\
&\Xi \text{DoorsOpening}; \Xi \text{ShockAbsorbers}; \Xi \text{Handle} \\
&st = u2 \\
&hPos = up \\
&\text{ranOp} = \{y\} \\
&\text{ran}\text{sa} \neq \{n\} \\
&st' = u4
\end{align*}
\]

The schema for reverting the order at this point is:

\[
\begin{align*}
&\Delta \text{StateCounter} \\
&\Xi \text{DoorsOpening}; \Xi \text{ShockAbsorbers}; \Xi \text{Handle} \\
&st = u2 \\
&hPos = down \\
&st' = d2
\end{align*}
\]
Z Specification of the Landing Gear System

\[
\begin{align*}
Up3E \quad & \neg (st = u2 \\
& \land \text{ranOp} = \{y\} \land 200 \leq \text{now} - \text{stEV} \land (100 \leq \text{now} - \text{stGEEV} \lor \text{stGEEV} = 0))
\end{align*}
\]

\[Up3 \equiv Up31 \lor Up32 \lor UpDown3 \lor Up3E\]

Since stopping the stimulation of electro-valves is subjected to timing restrictions (1 s between any two of them), the following schema takes the time marks concerning stopping the stimulation. The fourth step of the retracting sequences requires that all gears are locked up: ranRec = \{y\}.

\[
\begin{align*}
Up4Ok \quad &\Delta\text{GearsRetractingEV}; \Delta\text{EVsp}; \Delta\text{StateCounter} \\
&\Xi\text{GearsRetracting}; \Xi\text{Time}; \Xi\text{Handle} \\
&st = u3 \\
&hPos = up \\
&\text{ranRec} = \{y\} \\
&1000 \leq \text{now} - \text{spEV} \lor \text{spEV} = 0 \\
&\text{grEV}' = \text{idle} \\
&\text{spEV}' = \text{now} \\
&st' = u4 \\
&\text{stGREV}' = \text{stGREV}
\end{align*}
\]

The schema for reverting the order at this point is:

\[
\begin{align*}
UpDown4 \quad &\Delta\text{GearsRetractingEV}; \Delta\text{EVsp}; \Delta\text{StateCounter} \\
&\Xi\text{GearsRetracting}; \Xi\text{Time}; \Xi\text{Handle} \\
&st = u3 \\
&hPos = down \\
&\text{grEV}' = \text{idle} \\
&\text{spEV}' = \text{now} \\
&st' = d2 \\
&\text{stGREV}' = \text{stGREV}
\end{align*}
\]

\[
\begin{align*}
Up4E \quad &\Xi\text{GearsRetractingEV}; \Xi\text{EVsp}; \Xi\text{StateCounter}; \Xi\text{GearsRetracting}; \Xi\text{Time}; \Xi\text{Handle} \\
&\neg (st = u3 \land \text{ranRec} = \{y\} \land (1000 \leq \text{now} - \text{spEV} \lor \text{spEV} = 0))
\end{align*}
\]

\[Up4 \equiv Up4Ok \lor UpDown4 \lor Up4E\]
In Up5 is:

\[ 1000 \leq now - spEV \]

and not:

\[ 1000 \leq now - spEV \lor spEV = 0 \]

because to get to this schema the system has passed through schema Up4 where the gear retraction electro-valves were stopped, so \( spEV \) cannot be zero.

\[ \text{Up5Ok} \]

\[ \Delta\text{DoorOpeningEV}; \Delta\text{EVsp}; \Delta\text{StateCounter} \]

\[ \Xi\text{Time}; \Xi\text{Handle} \]

\[ st = u4 \]

\[ hPos = up \]

\[ 1000 \leq now - spEV \]

\[ doEV' = idle \]

\[ spEV' = now \]

\[ st' = u5 \]

\[ stDOEV' = stDOEV \]

The schema for reverting the order at this point is:

\[ \text{Down8} = = \text{Down8Ok} \lor \text{DownUp8} \lor \text{Down8E} \]

### 4.7 Time Advance

Although \( Z \) is not very well equipped to deal with time constraints and with real-time specifications in general [16], the following schema specifies that time always advances at a rate of one time unit (in this case one millisecond). Since \( \text{Tick} \) is always enabled it can be “executed” whenever there are no other operation being “executed”.

\[ \text{Tick} \]
\[ \Delta \text{Time} \]
\[ \text{now}' = \text{now} + 1 \]

### 4.8 Operations Concerning Health Monitoring

Health monitoring concerns with detecting situations that are deemed as anomalies. The anomalies concerning sensor validity are formalized in Sect. [4.5]. Then, this section contains the rest of the situations that can cause an anomaly. When an anomaly is detected (i.e. when the conditions for an anomaly become true) the software executes an action whose specification is the following schema:

\[ \text{Anomaly} = = [\Delta \text{CockpitA}|\text{lgskl} = \text{on}] \]

Recall that it has been assumed that the software stops when this action is executed and that \( \text{lgskl} \) represents both the actual light in the cockpit and an internal state variable whose value can be observed and modified by the software.

#### 4.8.1 Anomalies Related to the Analogical Switch

The first anomaly related to the analogical switch is produced when it is seen open 1 second after the handle position has changed. This situation is formalized in the following schema:
The analogical switch is open when \( as = y \) and \( lHPCh \) records the time of the last change of the handle if it is different than zero (because if it is equal to zero it means the handle was never changed).

If the conditions given in \( \text{AnalogicalSwitchM1} \) are not true, then the system has nothing to do. Therefore, a schema totalizing the operation is given:

\[
\text{AnalogicalSwitchM1E} \quad \Xi \text{AnalogicalSwitch}; \Xi \text{Handle}; \Xi \text{Time}
\begin{align*}
\neg (as = y \land 1000 \leq \text{now} - lHPCh \land lHPCh \neq 0)
\end{align*}
\]

The second situation related to the analogical switch that causes an anomaly is produced when it is seen closed 1.5 second after a time interval of 20 seconds during which the handle position has not changed. This is formalized by the following schema:

\[
\text{AnalogicalSwitchM2} \quad \Xi \text{AnalogicalSwitch}; \Xi \text{Handle}; \Xi \text{Time}
\begin{align*}
as = n \\
1500 \leq \text{now} - l20 \\
l20 \neq 0
\end{align*}
\]

The analogical switch is closed when \( as = n \) and \( l20 \) records the last time the handle position has not changed for 20 seconds. This schema is complemented as the previous one:

\[
\text{AnalogicalSwitchM2E} \quad \Xi \text{AnalogicalSwitch}; \Xi \text{Handle}; \Xi \text{Time}
\begin{align*}
\neg (as = n \land 1500 \leq \text{now} - l20 \land l20 \neq 0)
\end{align*}
\]

The full operation is specified as follows:

\[
\text{AnalogicalSwitchM ==}
\begin{align*}
((\text{AnalogicalSwitchM1} \lor \text{AnalogicalSwitchM2}) \land \text{Anomaly}) \\
\lor \text{AnalogicalSwitchM1E} \lor \text{AnalogicalSwitchM2E}
\end{align*}
\]

\( \text{AnalogicalSwitchM2} \) shows that it is necessary to specify an operation that monitors when 20 seconds have elapsed since the last change of the handle position. The next schema updates the variable \( l20 \) when that condition holds:
\[ \text{HandleNotChangedOk} \]
\[ \Delta \text{Handle}; \Xi \text{Time} \]
\[ \begin{align*}
\text{now} - lHPCh &= 20 \\
lHPCh &\neq 0 \\
l' &= \text{now} \\
hPos' &= hPos \\
lHPCh' &= lHPCh
\end{align*} \]

\[ \text{HandleNotChangedE} \]
\[ \Xi \text{Handle}; \Xi \text{Time} \]
\[ \neg (\text{now} - lHPCh = 20 \land lHPCh \neq 0) \]

\[ \text{HandleNotChanged} == \text{HandleNotChangedOk} \lor \text{HandleNotChangedE} \]

Perhaps, as Lamport suggests [25, Chapter 9], the following precondition for \text{HandleNotChanged} would be more realizable:

\[ |\text{now} - lHPCh| \leq 20 + \varepsilon \]

for some \( \varepsilon > 0 \). Or alternatively this one would be as realizable and closer to the real requirement:

\[ \text{now} - lHPCh \geq 20 + \varepsilon \]

### 4.8.2 Anomalies Related to the Hydraulic Circuit

The situations where an anomaly related to the hydraulic circuit is produced are the following:

- If the hydraulic circuit is still unpressurized 2 seconds after the general electro-valve has been stimulated, then an anomaly is detected. The following schema formalizes this situation:

\[ \text{HydraulicCircuitM1} \]
\[ \Xi \text{HydraulicCircuit}; \Xi \text{GeneralEV}; \Xi \text{Time} \]
\[ \begin{align*}
hc &= n \\
2000 &\leq \text{now} - \text{stGEV} \\
\text{stGEV} &\neq 0
\end{align*} \]

\[ \text{HydraulicCircuitM1E} \]
\[ \Xi \text{HydraulicCircuit}; \Xi \text{GeneralEV}; \Xi \text{Time} \]
\[ \neg (hc = n \land 2000 \leq \text{now} - \text{stGEV} \land \text{stGEV} \neq 0) \]
• If the hydraulic circuit is still pressurized 10 seconds after the general electro-valve has been stopped, then an anomaly is detected. The following schema formalizes this situation:

\[\text{HydraulicCircuitM2} \]
\[\exists \text{HydraulicCircuit}; \exists \text{GeneralEV}; \exists \text{Time} \]
\[ hc = y \]
\[ 10000 \leq now - spGEV \]
\[ spGEV \neq 0 \]

\[\text{HydraulicCircuitM2E} \]
\[\exists \text{HydraulicCircuit}; \exists \text{GeneralEV}; \exists \text{Time} \]
\[ \neg (hc = y \land 10000 \leq now - spGEV \land spGEV \neq 0) \]

Therefore, the full operation is as follows:

\[\text{HydraulicCircuitM} =\]
\[ (\text{HydraulicCircuitM1} \lor \text{HydraulicCircuitM2}) \land \text{Anomaly} \]
\[ \lor \text{HydraulicCircuitM1E} \lor \text{HydraulicCircuitM2E} \]

### 4.8.3 Anomalies Related to Doors Motion

There are four situations related to door motion that lead to an anomaly. Since these are quite similar in spirit to the previous ones there will be no comments.

\[\text{DoorsMotionM1} \]
\[\exists \text{Doors}; \exists \text{DoorOpeningEV}; \exists \text{Time} \]
\[ \text{randCl} \neq \{n\} \]
\[ 7000 \leq now - stDOEV \]

\[\text{DoorsMotionM1E} \]
\[\exists \text{Doors}; \exists \text{DoorOpeningEV}; \exists \text{Time} \]
\[ \neg (\text{randCl} \neq \{n\} \land 7000 \leq now - stDOEV) \]

\[\text{DoorsMotionM2} \]
\[\exists \text{DoorsOpening}; \exists \text{DoorOpeningEV}; \exists \text{Time} \]
\[ \text{randOp} \neq \{y\} \]
\[ 7000 \leq now - stDOEV \]
\[ \text{DoorsMotionM} \]

\[ \exists \text{DoorsOpening}; \exists \text{DoorOpeningEV}; \exists \text{Time} \]

\[ \neg (\text{ranOp} \neq \{y\} \land 7000 \leq \text{now} - \text{stDOEV}) \]

\[ \text{DoorsMotionM3} \]

\[ \exists \text{DoorsOpening}; \exists \text{DoorOpeningEV}; \exists \text{Time} \]

\[ \text{ranOp} \neq \{n\} \]

\[ 7000 \leq \text{now} - \text{stDCEV} \]

\[ \text{DoorsMotionM3E} \]

\[ \exists \text{DoorsOpening}; \exists \text{DoorClosingEV}; \exists \text{Time} \]

\[ \neg (\text{ranOp} \neq \{n\} \land 7000 \leq \text{now} - \text{stDCEV}) \]

4.8.4 Anomalies Related to Gears Motion

There are four situations related to gear motion that lead to an anomaly. Since these are quite similar in spirit to the previous ones there will be no comments.

\[ \text{GearsMotionM1} \]

\[ \exists \text{GearsRetracting}; \exists \text{GearsRetractingEV}; \exists \text{Time} \]

\[ \text{ranRec} \neq \{n\} \]

\[ 7000 \leq \text{now} - \text{stGREV} \]
\[ GearsMotionM1E \]
\[ \exists GearsRetracting; \exists GearsRetractingEV; \exists Time \]
\[ \neg (\text{ranRec} \neq \{n\} \land 7000 \leq \text{now} - \text{stGREV}) \]

\[ GearsMotionM2 \]
\[ \exists GearsRetracting; \exists GearsRetractingEV; \exists Time \]
\[ \text{ranRec} \neq \{y\} \]
\[ 10000 \leq \text{now} - \text{stGREV} \]

\[ GearsMotionM2E \]
\[ \exists GearsRetracting; \exists GearsRetractingEV; \exists Time \]
\[ \neg (\text{ranRec} \neq \{y\} \land 10000 \leq \text{now} - \text{stGREV}) \]

\[ GearsMotionM3 \]
\[ \exists GearsExtending; \exists GearsExtendingEV; \exists Time \]
\[ \text{ranExt} \neq \{n\} \]
\[ 7000 \leq \text{now} - \text{stGEEV} \]

\[ GearsMotionM3E \]
\[ \exists GearsExtending; \exists GearsExtendingEV; \exists Time \]
\[ \neg (\text{ranExt} \neq \{n\} \land 7000 \leq \text{now} - \text{stGEEV}) \]

\[ GearsMotionM4 \]
\[ \exists GearsExtending; \exists GearsExtendingEV; \exists Time \]
\[ \text{ranExt} \neq \{y\} \]
\[ 10000 \leq \text{now} - \text{stGEEV} \]

\[ GearsMotionM4E \]
\[ \exists GearsExtending; \exists GearsExtendingEV; \exists Time \]
\[ \neg (\text{ranExt} \neq \{y\} \land 10000 \leq \text{now} - \text{stGEEV}) \]

\[ GearsMotionM == \]
\[ (GearsMotionM1 \lor GearsMotionM2 \lor GearsMotionM3 \lor GearsMotionM4) \land \text{Anomaly} \]
\[ \lor GearsMotionM1E \lor GearsMotionM2E \lor GearsMotionM3E \lor GearsMotionM4E \]

Figure 7: Fastest script (part 3)
5 Test Case Generation from the Z Specification

Figures 5-7 list the Fastest script used to generate test case from the LGS specification. The resulting test conditions and abstract test cases automatically generated are listed in appendices A and B respectively.

6 Conclusions

After writing a Z specification of the LGS the Fastest tool was used to automatically generate almost 400 functional test cases. This shows that a formal specification helps not only to write the implementation from a solid document but that it also helps in verifying the former.
